Surface sediments

20. ABSTRACT (Continue on reverse side if necessary and identify by block number)

The long-term effects of beach nourishment on the benthic infauna and surface sediments of Panama City beaches were investigated. Forty-seven stations located on nine transects between West Pass and Philips Inlet, and two nourishment borrow sites were sampled in November-December 1979 and May 1980. The data collected were compared to prenourishment base-line information collected by Saloman (1976).

cont

Abiotic parameters, water temperature, dissolved oxygen and salinity were measured. Sediments were analyzed for particle-size distribution, percent organic carbon and percent carbonate.

Benthic macroinvertebrates were represented by 162 taxa of 14 major animal phyla. Species composition and faunal densities varied seasonally. Polychaetes and amphipods were the most abundant animal groups; a small number of species were dominant at nearly all stations. Species diversity was lowest in the swash zone and sandbar stations and highest offshore.

Sediment composition was similar to that of Saloman's (1976) study within limits of sampling and processing errors. Faunal composition was found to be different from 1976 but was attributed to normal seasonal and spatial variations. Based on benthic community analyses and sediment parameters, no significant differences were found between nourishment borrow sites and surrounding areas and in the nearshore areas where beach nourishment was conducted. No long-term adverse effects of beach nourishment were detected.

PREFACE

This report is published to provide coastal engineers the results of an investigation on the long-term effects of beach nourishment on the benthic infauna and surface sediments of Panama City Beach, Florida. The work was carried out under the coastal ecology research program of the U.S. Army Coastal Engineering Research Center (CERC).

The report was prepared by J.K. Culter and S. Mahadevan, Mote Marine Laboratory, Sarasota, Florida, under CERC Contract No. DACW72-79-C-0026. Participants during the investigation included K. Caraccia, F. Dalton, J. Drake, L. Eaton, L. Ferris, M. Gallo, G. McCallum, J. McIntosh, M. Messick, K. Moller, A. Rule, T. Russell, N. Stout, J. Weber, and R. Yarbrough.

The authors gratefully acknowledge the following scientists who helped during various aspects of this study: E. Nakumura, Director of the National Marine Fisheries Service, Gulf Fisheries Center, Panama City Laboratory, and the laboratory staff for their logistical aid during the fieldwork of this study; C.H. Saloman, also of the National Marine Fisheries Service, for his comments and assistance during the initial site survey; and Dr. W.H. Taft for suggestions concerning the sedimentology parts of the study. Assistance in the identification and verification of the various animal taxa collected was provided by Drs. R.T. Abbott (mollusca), E.D. Estevez (isopoda), R.W. Heard, Jr. (amphipoda, decapoda, and carideans), W. Price (cumacea), and C. Hunter (sipuncula).

E.J. Pullen, Chief, Coastal Ecology Branch, was the CERC contract monitor for the report, under the general supervision of R.P. Savage, Chief, Research Division.

Comments on this publication are invited.

Approved for publication in accordance with Public Law 166, 79th Congress, approved 31 July 1945, as supplemented by Public Law 172, 88th Congress, approved 7 November 1963.

To obtain Kelvin (K) readings, use formula: $K = (5/9)(F - 32) + 273.15$.

LONG-TERM EFFECTS OF BEACH NOURISHMENT ON THE BENTHIC FAUNA OF PANAMA CITY BEACH, FLORIDA

by
J.K. Culter and S. Mahadevan

I. INTRODUCTION

1. Background Information.

Coastal erosion is a major problem on many U.S. coastlines including the west coast of Florida. The westernmost beaches of Bay County on the Florida panhandle are considered critical areas of erosion (U.S. Army Engineer Division, South Atlantic, 1971; Bruno, 1971). Before the initiation of a nourishment program in 1976, the shoreline west of the entrance to St. Andrew Bay suffered considerable erosion for a number of years, causing many coastal structures to become vulnerable to storm damage. On 23 September 1975 Hurricane Eloise caused additional erosion and destroyed or undermined the foundations of numerous coastal structures (Saloman, 1976). Extensive areas of the Panama City and neighboring beaches were renourished in 1976 by hydraulically dredging offshore sands to replace the eroded beaches; however, observations made during this study inidicate that the bulk of the material deposited during the nourishment program has since eroded to prenourishment levels.

This study, which CERC contracted to the Mote Marine Laboratory, evaluates the long-term nourishment effects on the benthic fauna and surface sediments of the nearshore zone off Panama City Beach, Florida. The results of the study (1979-80) are compared to those obtained in the prenourishment study (1974-75) and in the study of short-term effects (1976-77) of the same beach (Saloman, 1976; Saloman, Naughton, and Taylor, in preparation, 1982).

Saloman's prenourishment study (1974-75) describes the area as having a diverse benthic macroinfauna with the number of species and faunal densities fluctuating seasonally. Species of polychaetes and amphipods dominated the fauna. The distribution of species was generally uniform along the beach with the number of species increasing offshore. There was no correlation of animal abundance to selected sedimentological parameters, which showed little spatial variation.

The short-term study of nourishment effects (Saloman, Naughton, and Taylor, in preparation, 1982) concluded that an initial destruction of the bottom community at the borrow pits was followed by rapid recovery virtually complete after 1 year. Minor differences in sediment parameters could be detected at the borrow pits after 1 year, but no distinction could be made between the faunas in and outside the borrow pits. The authors also concluded that normal seasonal variations of temperature and salinity could mediate changes in benthic diversity and abundance possibly masking or preventing detection of nourishment effects.

2. Study Area.

The study area, located on the northeastern shore of the Gulf of Mexico at Panama City, Florida, is bounded by the entrance to St. Andrew Bay (West Pass) and Philips Inlet, 34.3 kilometers to the west (Fig. 1). The easternmost part of the study area remains in a natural state (St. Andrews State Park) with extensive dunes backing the beach; the remainder of the area has been extensively developed with motels, condominiums, and support facilities occupying most of the beach front.

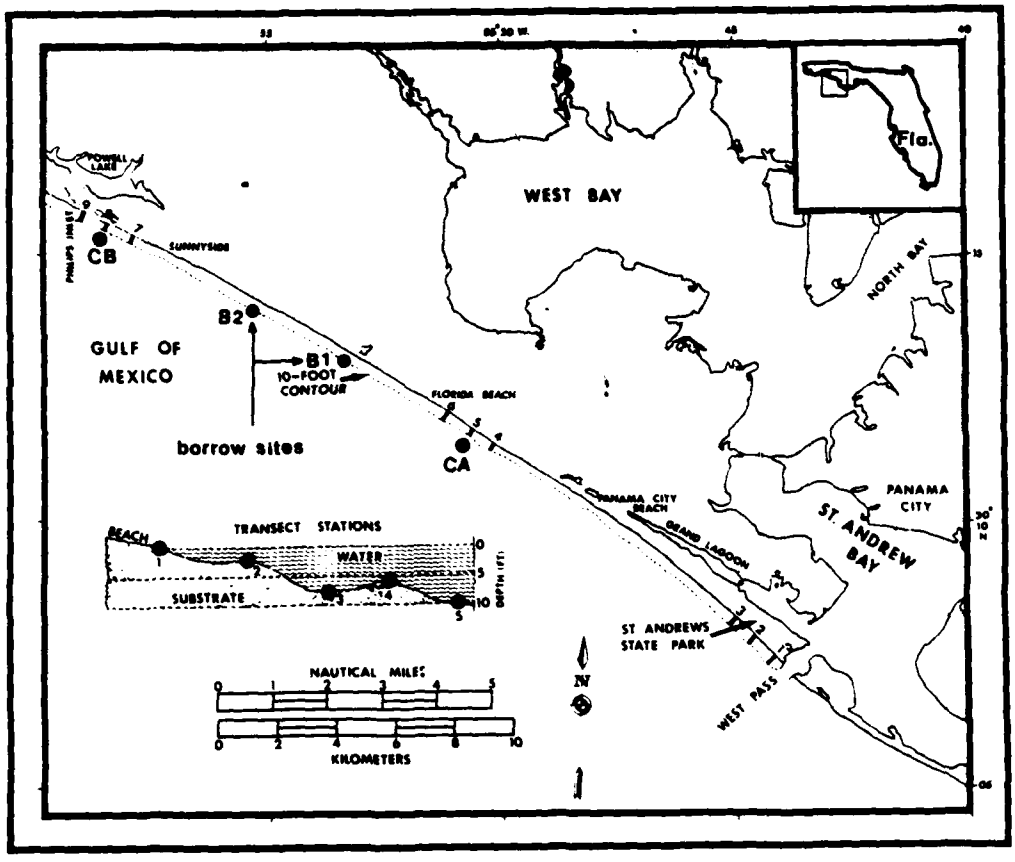

Figure 1. Study area, depicting transect and station locations in the Gulf of Mexico between West Pass and Philips Inlet.

The beaches along this part of the Gulf of Mexico have moderate wave energy with intensity increasing from east to west (Price, 1954; Tanner, 1960). The shoreline is fronted by two prominent offshore sandbars. The inner bar lies 23 to 91 meters offshore and is often sinuous and broken. The second bar, about 244 meters offshore, is continuous and uninterrupted. The depth of the first bar is generally less than 1.5 meters; the depth of the second bar is 3 to 4 meters. Just beyond the second bar the bottom slopes rapidly to about 9 to 10 meters. This slope continues to about 18 meters and then becomes more gradual. The continental shelf in this area is not nearly as wide as it is in most areas of the Gulf of Mexico.

The segment of gulf shoreline from Destin East Pass to St. Andrew Bay is unusual because it lacks the coastal barrier islands typical of Florida coastal geography (Bruun, Gerritsen, and Morgan, 1958). Kwon (1969) describes the physiography of the area as an erosional feature of the gulf coast. Prevailing winds in the area are from the southeast to south, generating an east-to-west longshore current. Balsillie (1975) summarized estimates of longshore transport for the beaches of the Florida panhandle. In the vicinity of St. Andrews Park the net longshore transport rates are estimated to range from 56,377 to 173,554 cubic meters per year.

3. Study Objectives.

This study provides information on the ecological relationship of the benthic fauna inhabiting natural beaches and offshore borrow areas. Infaunal community structure and surface sediment characteristics were examined following a beach nourishment program on the Panama City and nearby beaches. The data collected were compared with prenourishment base-line data to determine long-term effects of beach nourishment on benthic infauna. Specific objectives of the study were to

(a) quantitatively sample the benthic macroinfauna at 49 nearshore stations, including two borrow sites;

(b) identify the organisms collected to the lowest practical taxonomic unit;

(c) define the distribution, density, diversity, and other community parameters of the nearshore benthic infauna;

(d) collect surface sediment samples at each station and evaluate the granulometric composition as well as the organic carbonate content;

(e) sample during winter and summer months to determine seasonal variations; and

(f) compare the data collected with Saloman's (1976) data and evaluate the results in terms of beach nourishment effects.

4. Station Locations.

A total of 49 stations were sampled during this study. Forty-seven stations, located on nine transects in the Gulf of Mexico between West Pass and Philips Inlet, are the same as those sampled by Saloman (1976). The transects were positioned perpendicular to shore and each contained five stations (Fig. 1): station 1 in the swash zone; station 2 on the first sandbar; station 3 between the first and second sandbar; station 4 on the second sandbar; and station 5 seaward of the second sandbar in 3 to 4 meters of water. Stations CA and CB (control sites) were located in 9 to 10 meters of water off transects 5 and 8.

Locations of the nine transects along Panama City Beach are as follows: transect 1 is 274.3 meters west of the jetty at the entrance of St. Andrew

Bay in St. Andrews State Park; transect 2 is 30.5 meters east of the pier in St. Andrews State Park; transect 3 is offshore of the intersection of Lookout Street and Spyglass Street; transect 4 is offshore of the Holiday Inn West; transect 5 is offshore of the Fiesta Motel; transect 6 is offshore of the Fountainbleau Terrace Motel; transect 7 is offshore of the Sunnyside Motel; transect 8 is offshore of the Roundtower Motel; and transect 9 is offshore of Pinnacle Port. The motel names for transects 4 and 6 were reversed in Saloman (1976).

In addition to the 47 stations, 2 borrow sites that were dredged in July and August 1976, but have since filled in, were also sampled. Borrow site B1 is located about 6.4 kilometers southeast of Laguna Beach, offshore of the Ambassador Motel, 183 meters from Highway 98 in about 6.1 meters of water. The site is rectangular, 152 by 23 meters, and parallel to the beach. Borrow site B2 is located about 2.4 kilometers southeast of Laguna Beach in front of the Peppertree Motel (abandoned), 274 meters offshore of Highway 98 in about 6.1 meters of water. The site is rectangular, 229 by 128 meters, and is oriented diagonally to the shoreline. Stations CA and CB served as control stations for the borrow sites.

II. MATERIALS AND METHODS

1. Physical Parameters.

Temperature (in ^{o} Celsius), dissolved oxygen (in parts per million), and conductivity (in micromhos per centimeter) were measured at each station with a Hydrolab *in situ* physicochemical monitor. Where water depth was sufficient, readings were taken 0.5 meter below the surface as well as 0.5 meter above the bottom. Logbook entries for conductivity were corrected for temperature and converted to salinity (in parts per thousand). Dissolved oxygen readings were corrected for salinity.

2. Topography.

Using standard surveying techniques, beach profiles were constructed for each of the nine transect sites. Beginning landward at the surveying monuments, the profiles extended seaward to wading depth.

3. Sediment Characteristics.

At each station two sediment samples were taken with a 5.08-centimeter-diameter polyvinylchloride (PVC) core. The cores were inserted 10 to 15 centimeters into the substratum, removed and both ends corked. The samples were then transferred to 454-milliliter plastic jars with internal and external labels, frozen, and stored until analyzed. One sample from each station was processed for grain size, organic content, and carbonate content. The second sample served as a backup.

Laboratory analysis of sediment samples is schematically shown in Figure 2. Details of the procedures are as follows:

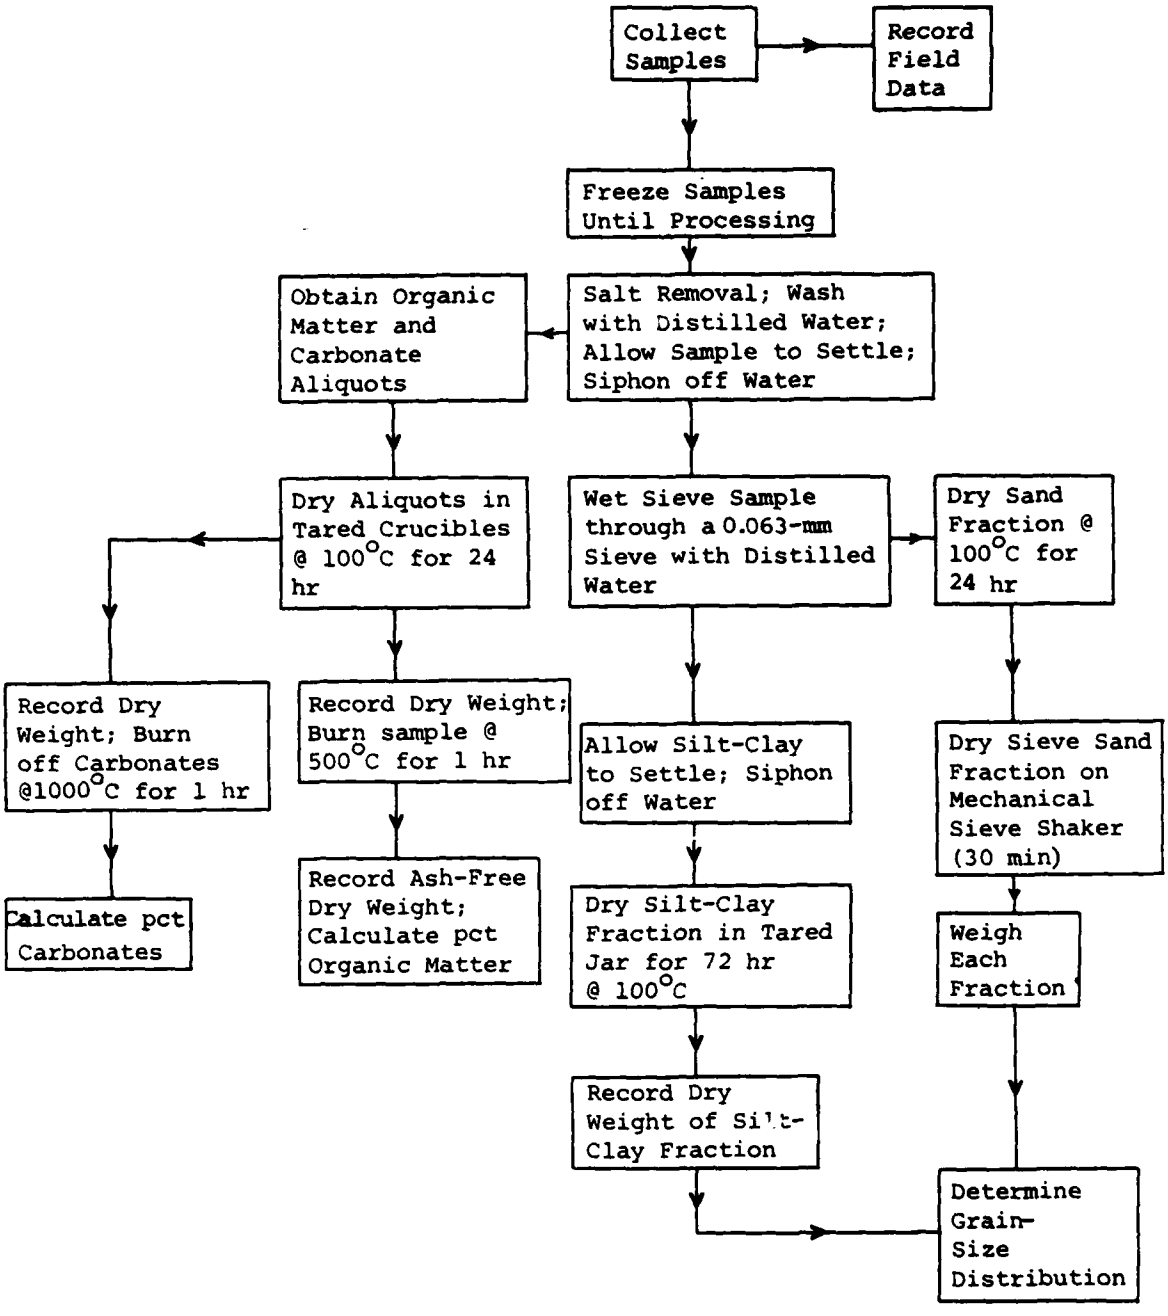

Figure 2. Schematic of sediment analysis procedures.

(a) Grain-size analysis was performed by sieving a dried sample aliquot through a series of 20-centimeter-diameter nested sieves of 1-phi mesh intervals (Wentworth scale) for 30 minutes. The sample was first rinsed with distilled water to remove salt and sieved wet with a 0.063-millimeter mesh to remove any silt-clay fractions (also dried and weighed).

(b) Organic carbon present in each sample was determined by combusting a previously dried sample at 500° Celsius for 1 hour. The loss due to ignition was considered to be the organic carbon content.

(c) Carbon as present in carbonate compounds was determined by heating a sample (organic carbon previously burned off) to 1000° Celsius for 1 hour. The weight loss was considered to be the amount of carbon, as carbonates, present in the sample.

Various data analysis procedures were used in the statistical analyses (Tables 1 to 4) of the sediment samples. Organic carbon and carbonate values were calculated and presented as percentages of the total sample. Statistics on the grain-size distribution were performed using the following formulas, where phi ($\emptyset$) = $-\log_2 x$; x = particle size in millimeters:

(a) Median grain size, Md, is the point at which half of the particles by weight are coarser and half are finer. It is the diameter corresponding to the 50 percent mark on the cumulative curve.

(b) Mean grain size, Mz, is the overall size measure (Folk, 1974).

$$Mz = \frac{\emptyset 16 + \emptyset 50 + \emptyset 85}{3}$$

(c) Inclusive graphic standard deviation (sorting coefficient), σ, is the measure of uniformity or sorting (Folk, 1974).

$$\sigma = \frac{\emptyset 84 - \emptyset 16}{4} + \frac{\emptyset 95 - \emptyset 5}{6.6}$$

(d) Inclusive graphic skewness, Sk, measures the degree of asymmetry of the particle distribution curve, taking into account the skewness of the tails of the curve as well as the central part. It is independent of the sorting of the sample. A symmetrical curve has a skewness of zero; a positively skewed curve indicates an excess of fine material; a negatively skewed curve indicates an excess of coarse sediments (Table 3) (Folk, 1974).

$$Sk = \frac{\emptyset 16 + \emptyset 84 - 2\emptyset 50}{2\ (\emptyset 84 - \emptyset 16)} + \frac{\emptyset 5 + \emptyset 95 - 2\emptyset 50}{2\ (\emptyset 95 - \emptyset 5)}$$

(e) Graphic kurtosis, Kg, is the ratio between the sorting in the tails of the granulometric curve and the sorting of the new central part of the curve (Folk, 1974).

$$Kg = \frac{\emptyset 95 - \emptyset 5}{2.44\ (\emptyset 75 - \emptyset 25)}$$

Table 1. Sediment classification by particle size (Wentworth classification).

Class	Grain size	
	Phi	Millimeters
Gravel	<-1	>2.0
Very coarse sand	0	>1.0 ≤2.0
Coarse sand	1	>0.5 ≤1.0
Medium sand	2	>0.25 ≤0.5
Fine sand	3	>0.125 ≤0.25
Very fine sand	4	>0.0625 ≤0.125
Silt clay	> 4	≤0.0625

Table 2. Degree of sediment sorting based on inclusive graphic standard deviation (Folk, 1974).

Standard deviation	Degree of sorting
<0.35 Ø	Very well sorted
0.35 Ø - 0.50 Ø	Well sorted
0.50 Ø - 0.71 Ø	Moderately well sorted
0.71 Ø - 1.00 Ø	Moderately sorted
1.00 Ø - 2.00 Ø	Poorly sorted
2.00 Ø - 4.00 Ø	Very poorly sorted

Table 3. Classification of sediment by skewness (Folk, 1974).

Sk values	Degree of skewness
+1.00 - +0.30	Strongly fine-skewed
+0.30 - +0.10	Fine-skewed
+0.10 - -0.10	Near symmetrical
-0.10 - -0.30	Coarse skewed
-0.30 - -1.00	Strongly coarse-skewed

Table 4. Classification of sediment by kurtosis (Folk, 1974).

Kg values	Degree of kurtosis
<0.67	Very platykurtic
0.67 - 0.90	Platykurtic
0.90 - 1.11	Mesokurtic
1.11 - 1.50	Leptokurtic
1.50 - 3.00	Very leptokurtic
>3.00	Extremely leptokurtic

4. Benthic Fauna.

a. Field Procedures. Benthic fauna was sampled with a stainless-steel plug sampler (Fig. 3) covering a surface area of 0.016 square meter and penetrating to a depth of 23 centimeters. This was the same type coring device used by Saloman (1976). The top of the core was covered with 0.5-square millimeter mesh, stainless-steel screen to prevent loss of organisms. In operation the sampler is inserted into the substratum; the sediments on the outside of one side of the sampler are removed, and the sampler tilted and lifted out with a hand covering the bottom. At stations with a water depth greater than 1.2 meters the sampler is operated by a diver who removes the core, inverts it, and places it in a metal basket. When four cores are obtained, the basket is hauled to the surface vessel, where the samples are extruded into labeled 5-gallon (19 liters) plastic buckets. Samples taken in less than 1.2-meter depths are obtained by wading and returning to the beach for processing.

Five plug samplers were taken at each station: four samples for faunal analysis and one as a backup in case of a loss of a processed sample. Onshore the samples were washed through a box sieve with a mesh of 0.701 square millimeter. The material retained on the sieve was placed in a plastic jar with both internal and external labels. A 10 to 15 percent solution of magnesium chloride in seawater was added to the jars to relax the organisms in order to reduce fragmentation upon preservation. After relaxation, a 10 percent formalin-seawater buffered solution containing rose bengal stain (to facilitate sorting) was added to the samples. Samples were transferred to 70 percent isopropyl alcohol within a week of initial preservation.

b. Laboratory Procedures. In the laboratory faunal samples were sorted under a stereozoom binocular dissecting microscope. Taxonomic identifications were performed under the binocular dissecting scope or a binocular compound microscope. Identifications of species were accomplished with the use of descriptive literature and a set of reference specimens from Saloman (1976). Additionally, taxonomic experts were utilized to either identify or confirm identifications of selected taxa.

c. Data Analysis Procedures. Numerical indices were chosen which have a widespread use in scientific literature and provide summaries of data, and which would aid comparisons with Saloman's (1976) data.

Faunal density estimates are reported as numbers of individuals per square meter. Values were computed by dividing the total number of individuals found at a station (for four replicates) by the total area sampled (0.0624 square meter).

Species richness was considered to be the total number of species found at each station for all replicates.

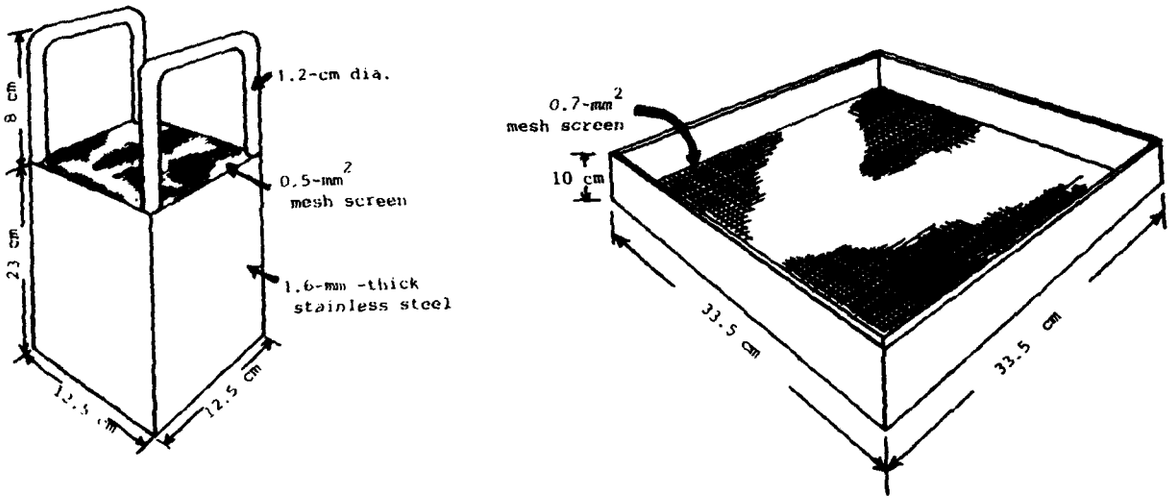

Figure 3. Sieve and plug sampler used for quantitative benthic studies.

Menzies, George, and Rowe (1973) define species diversity as a concept in community ecology which refers to the heterogeneity (or lack of it) in a community or assemblage of organisms. Thus, diversity is dependent upon the number of species present (species richness, S) and the distribution of individuals among species (equitability or evenness). Another definition of diversity is simply the number of species found in a unit area (Whittaker, 1972). Indices to measure diversity, species richness and equitability are so numerous that confusion exists (e.g., Hairston, 1964; Sanders, 1968; Hurlbert, 1971; Whittaker, 1972; Fager, 1972; Peet, 1974; Pielou, 1975; Smith, et al., 1979). The proliferation of indices prompted Hurlbert (1971) and Peet (1974) to recommend discarding diversity as a measure in ecological studies. However, placed in the proper perspective, diversity indices have been shown to be useful in "bioenvironmental" studies (Boesch, 1972; Borowitzka, 1972; Swartz, 1972; Pearson, 1975; Swartz, 1978). In this study the data analysis is restricted to the two commonly used diversity indices: the Shannon-Weaver index (Shannon and Weaver, 1963) and the Gini's index (Gini, 1912; Simpson, 1949).

(1) The Shannon-Weaver Index of Diversity. This index is based on information techniques, where diversity is equated to the amount of uncertainty which exists regarding the species identity of an individual selected at random from a community. The more species and the more evenly their representation, the greater the uncertainty and hence, the greater the diversity. The computational formula for Shannon's index is

$$H' = C/N \left(N \log_{10} N - \sum_{i=1}^{s} n_i \log_{10} n_i\right)$$

where C = 2.3026 (for "nats", units expressed as natural logarithms), N is the total number of individuals, and n_i the number of individuals in the ith species. Lloyd, et al. (1968) presented the functions of "$n\log_{10}n$" for all integers from n = 1 to n = 1050 to simplify the use of Shannon's index.

(2) Gini's Index of Diversity. This index is a measure of the dominance in a sample. Though it is usually insensitive to rare species, it has been used commonly as a diversity index. The computational formula for dominance diversity (Simpson, 1949) is

$$DM = \sum_{i=1}^{s} n\,(n-1)/N(N-1)$$

and complemental or actual diversity, d = 1 - DM (Gini, 1912).

(a) Equitability. Equitability is considered a component of diversity in that it provides an idea about the evenness of species distribution at a site. Usually, a positive correlation exists between diversity and equitability (De Jong, 1975), i.e., a high equitability would indicate a high diversity. Traditionally, high equitability and diversity have been considered to indicate a "healthy condition" of the fauna. Reduction of equitability usually occurs with an increase in oligomixity (i.e., dominance by few species). Pielou's (1966) method of measuring equitability was used in this study. The computational formula is

$$J' = H'/\log_e s$$

(b) Faunal Similarity. A number of coefficients for measuring faunal similarities are available (Sanders, 1960; Horn, 1966; Whittaker, 1967; Lie and Kelly, 1970; Bray and Curtis, 1975; Grassle and Smith, 1976). However, most of the available coefficients consider only the number and rank of common species and not the distribution of individuals. The Morisita's index (Morisita, 1959), which takes into consideration both the number of species in common and the number of individuals shared, is utilized in this study. Many authors in the past have used this index with a greater degree of success than other overlap coefficients (Ono, 1961; Barnard, 1970; Mauchline, 1972; Bloom et al., 1972; Gage and Geekie, 1973; Menzies, 1973; Paul, 1973; Farrell, 1974; Marum, 1974; Gage, 1975; Mahadevan, 1979). The computational formula for the Morisita's index is

$$C\lambda = 2 \sum_{i=1}^{s} n_{1i}\, n_{2i} / (\lambda_1 + \lambda_2)\, N_1\, N_2$$

where

$$\lambda_1 = \sum_{i=1}^{s} \frac{n_{1i}\,(n_{1i}-1)}{N_1\,(N_1-1)}$$

and

$$\lambda_2 = \sum_{i=1}^{s} \frac{n_{2i}\,(n_{2i}-1)}{N_2\,(N_2-1)}$$

where N_1 and N_2 are the total number of individuals in sample one and two, respectively. n_{1i} and n_{2i} are the number of individuals in the ith species of sample one and two, respectively. The value of $C\lambda$ is about one when the two samples are identical and zero when no common species are present. The index is relatively free from sample size effects.

Faunal similarity comparisons were conducted between Saloman's (1976) collections and this study's collections. Each station was considered as a composite over nine transects.

III. RESULTS

1. Physical Parameters.

a. Present Study. Values for water temperature, salinity, and dissolved oxygen concentration for each station are presented in Table 5, for November-December 1979, and in Table 6 for May 1980. Temperatures during the November-December sampling ranged from 16.5° to 21.0° Celsius. The lower temperatures were usually recorded in the colder, early morning hours before the water became mixed and warmed by solar radiation. Bottom temperatures at the deeper stations were generally slightly warmer than surface temperatures. Variation of temperature was less during May with values ranging from 24.0° to 26.0°Celsius.

Salinity during the November-December sampling ranged from 32.5 to 35.5 parts per thousand, typical of open gulf waters not strongly influenced by coastal runoff. Salinities during May were slightly lower, ranging from 29.0 to 32.0 parts per thousand. The extremely low values recorded, 14.5 to 27.0 parts per thousand (Table 6), are believed to be due to instrument malfunction.

Table 5. Water temperature, salinity, and dissolved oxygen data for the November-December 1979 sampling at all stations.

Station	Temperature (°C)		Dissolved Oxygen(ppm)		Salinity (ppt)

+[1] indicates water too shallow for two readings.
*[2] indicates data were not obtained due to very rough seas.
[3] indicates probable instrument malfunction.

Dissolved oxygen values were higher in November-December than in May, reflecting the colder water temperatures. For November-December, dissolved oxygen values ranged from 7.1 to 8.6 parts per million and for May they ranged from 4.8 to 5.8 parts per million. Overall, the highest dissolved oxygen values were recorded at the surface of the shallow stations. All stations appeared to have relatively high dissolved oxygen values (near saturation), indicating that dissolved oxygen would not be a limiting factor in the distribution and abundance of the benthic fauna in the study area.

Spatially, all physical parameters varied very little for both sampling periods. Additionally, temperature, salinity, and dissolved oxygen were not indicative of stressful conditions. Therefore, they are not considered as controlling factors in the distribution of benthic fauna within the study area, provided the observations made during November-December and May are characteristic of conditions during the remainder of the year.

b. Comparison to Saloman's (1976) Study. Dissolved oxygen was not measured during Saloman's (1976) study. The values for temperature and salinity recorded during this study compare very favorably to the data compiled by Saloman (1976). The ranges of salinity and temperature are nearly identical for comparable sampling dates. As observed during this study, Saloman's data exhibited only low levels of spatial variation.

2. Topography.

Beach profiles were constructed for each of the nine transects (Fig. 4). Two additional stations sampled were used as nourishment borrow sites in July and August 1976. A special effort was made at these stations to detect any irregularities of bottom profile or type of substrata. Numerous nearshore to offshore as well as shoreline parallel bathymetric profiles were run over each borrow site to detect any depressions or irregular contours. No depressions or changes in bottom type could be detected either by fathometer traces or visual inspection by divers. The borrow sites were indistinguishable from undisturbed areas within the limits of detection methods used.

3. Sediment Characteristics.

a. Present Study. A total of 98 sediment samples from the November-December 1979 and May 1980 collections were analyzed for particle-size distribution, organic carbon, and carbonate. Summaries of the results of these analyses are presented in Table 7 (November-December 1979) and Table 8 (May 1980). A complete breakdown of the particle-size distribution by phi interval is given in Appendix A. Little variation was evident on a seasonal basis. For the November-December sampling mean grain size ranged from 1.35 to 2.50 phi; mean grain size ranged from 1.44 to 2.91 phi for the May sampling. Spatially, sediments gradually changed from coarser to finer grain size on transects from the shore to the outer stations. This change is due primarily to a shift from medium to fine sand particles. Most of the stations for both sampling periods were moderately to moderately well sorted, being somewhat coarse-skewed. The bulk of the sediments within the study area consisted of fine, medium, and coarse quartz sand.

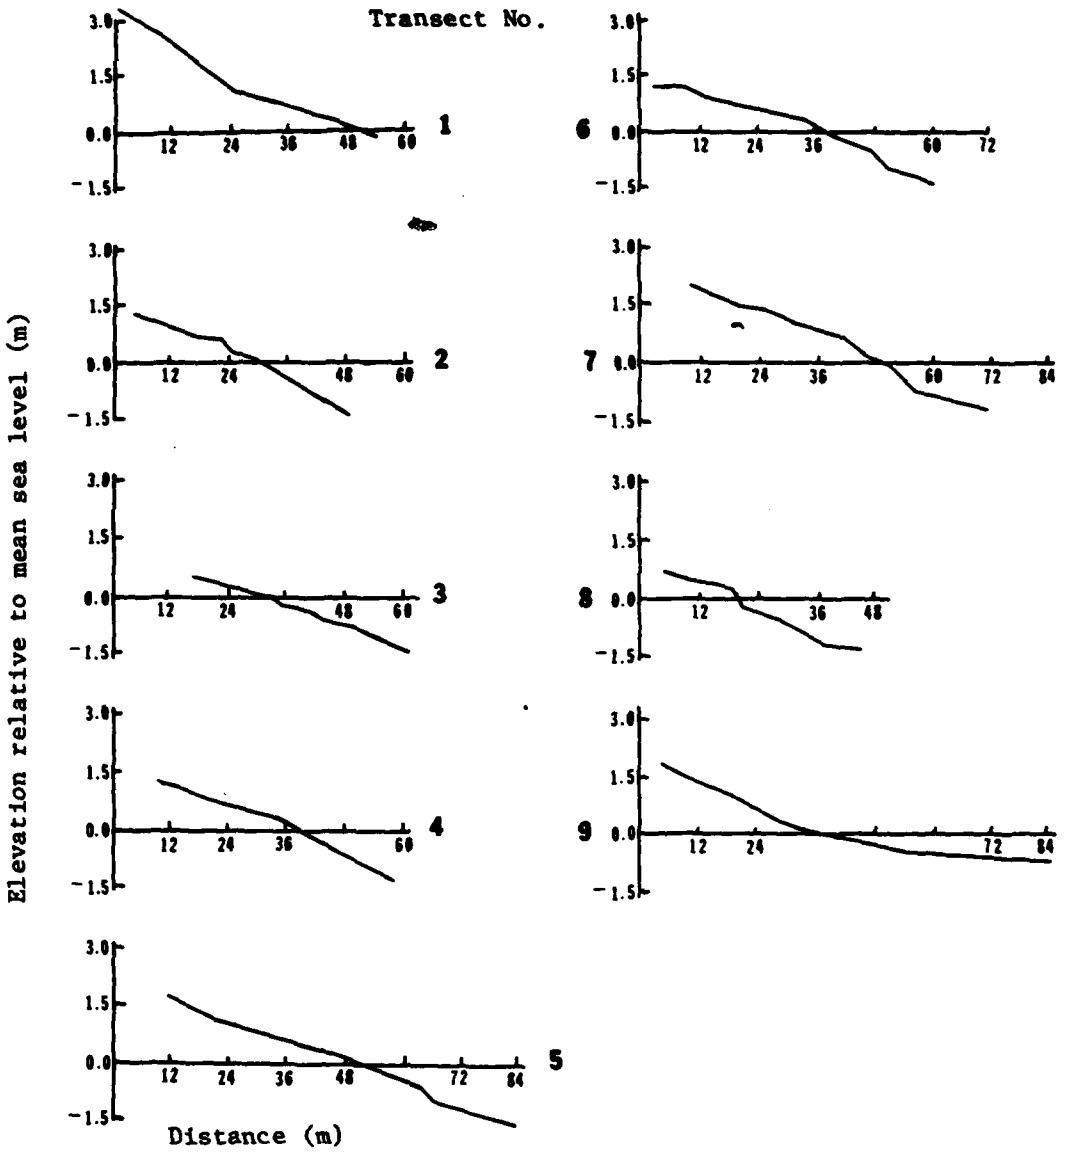

Figure 4. Beach profiles for the nine transect locations on the Panama City beaches, May 1980.

Table 7. Sediment parameters for all stations for the November-December 1979 sampling.

There was very little silt-clay material in the surface sediments of the study area, ranging from 0.00 to 0.22 percent in November-December and 0.00 to 0.28 percent in May. There were no strong nearshore-offshore trends in the percentage of silt-clay.

The percentages of carbon within the sediments for both organic carbon and carbonate were also very low with little spatial or temporal variation. Organic carbon ranged from 0.03 to 0.52 percent in November-December and 0.03 to 0.30 percent in May. Carbon as carbonate ranged from 0.00 to 1.36 percent in November-December and from 0.02 to 2.23 percent in May. There were no strong nearshore-offshore trends for either organic carbon or carbonate. However, the nearshore stations 1 and 2 seemed to exhibit overall lower organic carbon values.

There were no discernible east-west trends among the sediment parameters. The surface sediments of the entire study area consist of fine to medium coarse quartz sands, containing very low levels of silt-clay, organic carbon, and carbonate.

The sediment parameters of the borrow sites B1 and B2 did not differ markedly from the control stations CA and CB, with the exception of a slightly greater percentage of fine sand at the borrow sites.

b. Comparisons to Saloman's (1976) Study. Comparisons of mean grain size, percent silt-clay, percent organic carbon and percent carbonate between this study and Saloman's (1974-75) data are presented in Tables 9 and 10. Only minor differences were found between the two studies. There is a slight but consistent increase of mean grain size (phi) from 1974-75 to 1979-80, indicating a slightly finer substrate composition in 1979-80 (see Fig. 5). However, the percentage of silt-clay material was apparently greater during 1974-75.

For both sampling periods the finest sediments (based on mean grain size) were recorded from the borrow sites, although they had nearly the lowest levels of silt-clay material. Comparisons of silt-clay percentages are shown in Figure 6.

The organic carbon and carbonate percentage values were higher during 1979-80 (0.03 to 0.52 percent organic carbon, 0.00 to 2.23 percent carbonate) than during 1974-75 (0.01 to 0.16 percent organic carbon, 0.00 to 0.77 percent carbonate). Comparisons are shown in Figures 7 and 8.

Only relatively small changes were found in the various sediment parameters between the current and 1974-75 data. Slight differences in processing techniques by the respective investigators and normal sampling variation would account for the observed changes.

4. Benthic Fauna.

a. Present Study. A total of 5,044 individuals, representing 128 taxa, were collected from 28 November to 1 December 1979 at the 49 benthic

Table 9. Comparison of mean grain size (phi), percent silt-clay, percent organic carbon and percent carbonate between November 1974 and November-December 1979 (Saloman, 1976) for all stations.

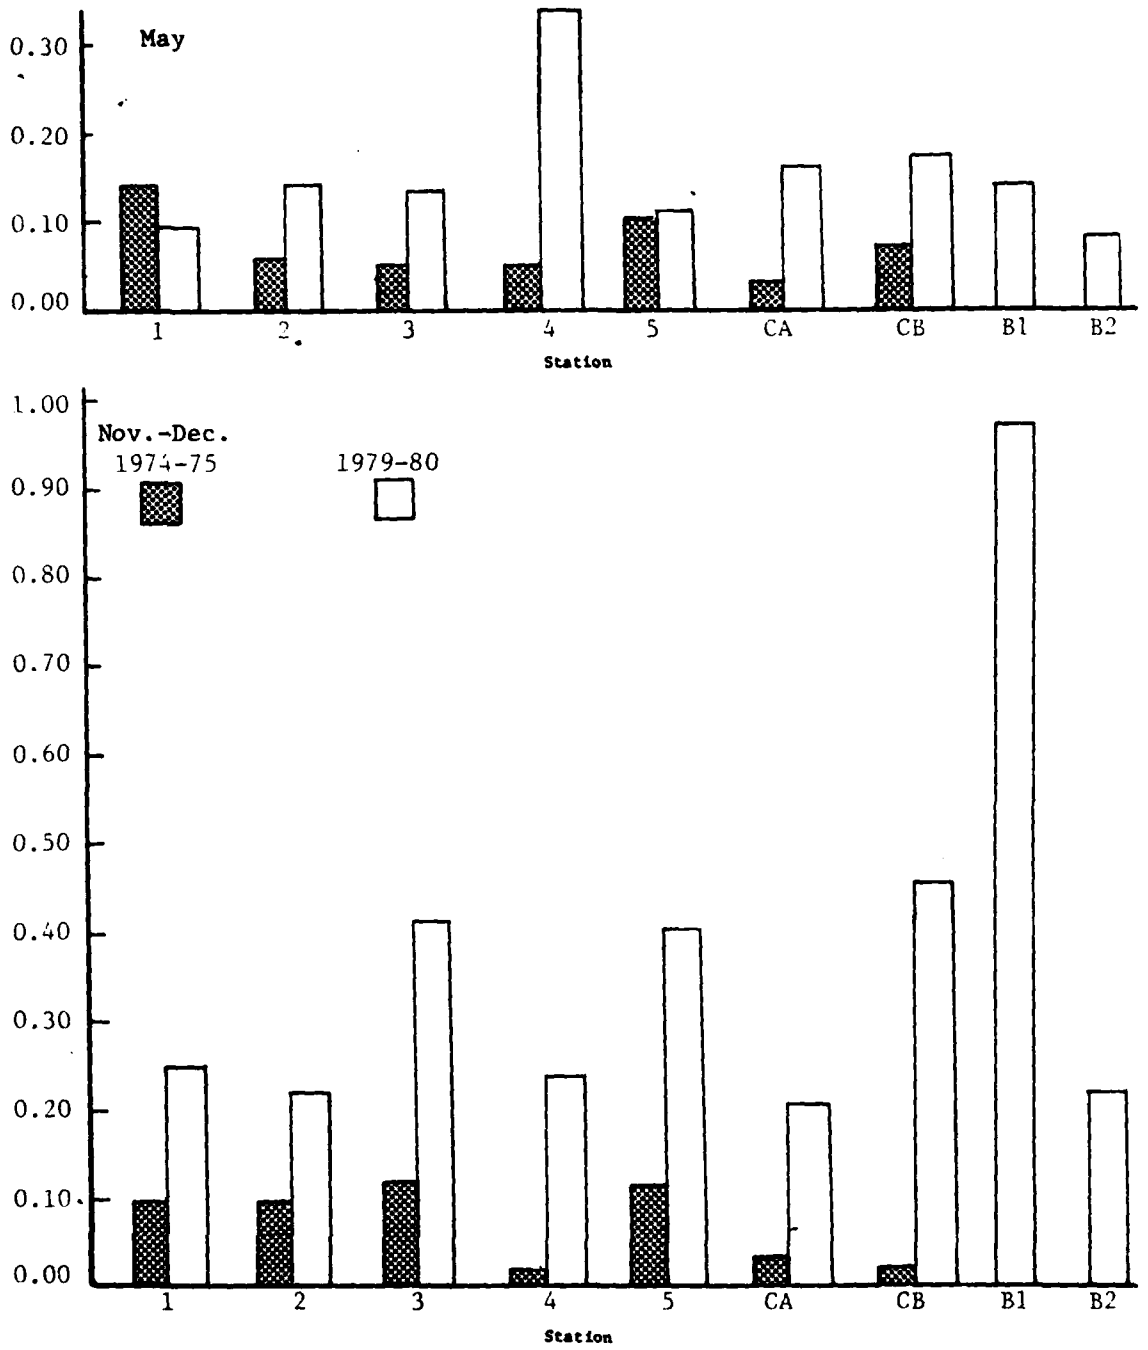

Figure 8. Graphic comparisons of carbonate percentages for May and November-December between the 1974-75 and 1979-80 collections.

stations; 5,959 individuals, representing 125 taxa, were collected from 19 to 23 May 1980. Composite species lists and faunal counts for all stations for each sampling period are presented in Appendix B. A checklist of species collected during this study (Table 11) lists 162 taxa representing 14 animal phyla.

(1) Species Composition. Of the 128 taxa collected in November-December, the most abundant group was the polychaetes (36 species), followed by bivalves (14 species), gastropods (13 species), amphipods (10 species), and brachyurans (10 species). For May, the same groups were again dominant: polychaetes (36 species), gastropods (15 species), amphipods (12 species), bivalves (11 species), and brachyurans (9 species). These data are presented in Table 12. Other major groups were represented by few species and composed only a small percentage of the total fauna.

For November-December, the most abundant species at transect stations 2 to 5 was the polychaete *Paraonis fulgens* (25, 30, 42, and 22 percent of total fauna). For station 1 the polychaete *Scolelepis squamata* was dominant (55 percent) At station 2 the bivalve *Donax texasianus* (15 percent), the amphipod *Haustorius* n. sp., a new undescribed species (11 percent), and the mysid *Boumaniella* spp. (11 percent) were also dominant taxa. The amphipods *Acanthohaustorius* sp., *Protohaustorius* n. sp., and *Pseudohaustorius* n. sp., were important faunal components at stations 3, 4, and 5. Table 13 presents the dominant fauna for stations 1 to 5 for the November-December sampling. Table 14 lists the dominant fauna for stations CA and CB. These stations were characterized by a lower level of oligomixity. The amphipod *Protohaustorius* n. sp. (15 percent) was the most abundant species at station CA; an unidentified nematode (22 percent) the amphipod *Pseudoplatyischnopus* n. spp. (15 percent) and an unidentified oligochaete (14 percent) were dominant at station CB.

For May (Table 15) the polychaete *Scolelepis squamata* (90 percent) was singly dominant at station 1 and was also abundant at station 2 (21 percent). *Paraonis fulgens* was again abundant at stations 3 (10 percent), 4 (42 percent), and 5 (18 percent). Also common at station 3 was the echinoderm *Mellita quinquiesperforata* (15 percent), the amphipod *Protohaustorius* n. sp. (13 percent), and the polychaete *Spiophanes bombyx* (10 percent); at station 4 the amphipods *Acanthohaustorius* sp. (8 percent) and *Protohaustorius* n. sp. (9 percent) were common; and at station 5 the amphipod *Protohaustorius* n. sp. (28 percent) and the polychaete *Nephtys picta* (7 percent) were abundant. Stations CA and CB showed a higher level of oligomixity for May than for November-December, but again it appeared lower than for the transect stations. At station CA the amphipod *Protohaustorius* n. sp. (27 percent) and the polychaete *Myriochele oculata* (14 percent) were abundant; at station CB the bivalve *Pitar simpsoni* (35 percent) and the amphipods *Pseudoplatyischnopus* n. spp. (12 percent) and *Protohaustorius* n. sp. (12 percent) were the most numerous.

[1]No comparable data.

Table 14 presents the dominant species data for borrow sites B1 and B2 for both the November-December and May samplings. Both stations exhibited relatively high levels of oligomixity in November-December with more than 80 percent of fauna represented by only four species (site B1) and three species (site B2). The faunal distribution improved significantly by May with the number of species representing more than 80 percent of the fauna doubling for each site.

Faunal composition between corresponding stations of the nine transects did not vary substantially for either sampling period. Examination of the composite lists and faunal counts (App. B, Tables B-1 and B-2) shows that species numbers varied little between stations. Faunal counts showed some variation between corresponding stations. However, the largest variations were usually due to a greater or lesser abundance of a dominant species. The overall pattern of faunal composition is dominance by several species over all corresponding stations with "rare" species distributed rather uniformly over all stations.

(2) Species Richness. The number of species found at each station is presented in Tables 16 and 17 for November-December and May, respectively. Species richness ranged from 6 to 39 species (stations 7-1 and CB) for November-December and 4 to 43 species (stations 9-1 and CB) for May. Generally, the number of species increased with increasing distance from shore for both sampling periods. Control stations CA and CB exhibited the greatest number of species for both sampling periods. The borrow sites generally had species numbers comparable to stations 2 or 3 of the transects. Overall, there was relatively little variation in species numbers between comparable stations of the nine transects (see Tables 16 and 17).

(3) Faunal Density. For the November-December sampling period faunal density ranged from 192 organisms per square meter at station 1 on transect 4 to 4,912 organisms per square meter at station 4 on transect 8. For May the density ranged from 336 organisms per square meter at station 1 on transect 8 to 6,064 organisms per square meter at station 1 on transect 1. Faunal density estimates for all stations are listed in Tables 18 and 19. Faunal densities for stations 1, 2, 3, CA and CB were generally greatest in May with the exceptions of stations 2-1, 8-1, 9-1, 1-2, 6-3 and 7-3, which exhibited the greatest densities in November-December. Stations 4, 5 and the borrow sites B1, B2 had the highest faunal densities in November-December with the exceptions of stations 2-4, 3-4, 9-4, 2-5, 3-5, and 4-5 having greater numbers in May. Overall, the nearshore stations and CA and CB exhibited greater faunal densities in May than November-December with the offshore stations and borrow sites having greatest densities in November-December. Variation among corresponding stations over the nine transects was largest when the faunal densities were greatest (e.g., variations in faunal density for stations 1, 2 and 3 were largest in May, corresponding to greatest faunal densities).

Table 18. Comparison of faunal density (number of organisms per square meter) between November 1974 and November-December 1979 for all stations.

(4) Species Diversity and Equitability. Species diversity (Shannon-Weaver H') and equitability values (Pielou's J') are presented in Table 20 (November-December 1979) and Table 21 (May 1980). Diversity values ranged from 0.47 to 3.22 (stations 1-1 and CA) for November-December and 0.15 to 2.85 (stations 1-1 and 2-3) for May. For transect stations 1, 2, and 3 and stations CA and CB, diversity values generally decreased from November-December to May. Transect stations 4 and 5 showed the least amount of seasonal change. Borrow sites B1 and B2 were unusual in exhibiting a pronounced increase in diversity from November-December to May. Diversity values for transect stations 1 and 2 were generally much lower than all other stations, for both sampling periods. Station 4 exhibited lower diversity values than stations 3 or 5.

Equitability values were generally quite high (>0.60) with the exception of transect station 1, indicating a relatively low level of oligomixity within the study area.

Table 22 lists values for Simpson's diversity index (λ) for transect stations 1 to 5 for all nine transects, as well as stations CA and CB and borrow sites B1 and B2. In this case a low λ value indicates a high diversity. This measure shows the trends illustrated in Tables 20 and 21, i.e., stations 1 and 4 have the lowest diversities, with diversity increasing slightly at the offshore stations.

b. Comparison of Faunal Parameters to Saloman's (1976) Study. Comparisons of the species and number of individuals collected for all 47 stations between the present study (1979-80) and Saloman's study (1974-75) are given in Appendix C. The major differences are given below.

(1) Species Richness. For November-December comparisons the number of species collected at each station was greater in 1979 than in 1974, with the exception of station 1-5, with 16 species collected during both studies (Table 16). For May comparisons, 29 stations exhibited more species during 1980, 17 exhibited less, and 1 remained the same (Table 17). The number of species at a station (averaged over 9 transects for stations 1 to 5) is depicted in Figure 9 (November-December) and Figure 10 (May).

(2) Faunal Density. For November-December comparisons faunal densities were mostly greater in 1979 than 1974 (35 stations with faunal densities in 1979 greater than 1974, 12 less than 1974; see Table 18). For May the faunal densities were always higher in 1975 than 1980 (Table 19). This was primarily caused by the extreme abundance of some species in 1975: the bivalve *Donax texasianus* (stations 1 to 4) and the amphipods *Acanthohaustorius sp.* (stations 3, 4, and 5) and *Protohaustorius n.* (stations 3, 4, and 5). Faunal density comparisons for each station (averaged over 9 transects for stations 1 to 5) are exhibited in Figure 9 (November-December) and Figure 10 (May).

Table 20. Comparisons of equitability values (Pielou's J') and Shannon-Weaver diversity values (H') between the November 1974 (Saloman, 1976) sampling and the November-December 1979 collections.

(3) Species Composition. An examination of the tables in Appendix C and Tables 13, 14, and 15 shows that there is a great deal of difference between the community composition of 1974-75 and 1979-80. A superficial examination of Tables 13, 14, and 15 indicates that at most of the stations the dominant species have changed. However, a more detailed look at the composite species lists for 1979-80 (see App. B) and the 1974-75 list (Saloman, 1976) indicates that few species were unique to either study. Not evident from the data in these tables is the fact that nearly all the species reported for this study were also reported by Saloman (1976), although not for corresponding sampling periods.

(4) Species Diversity and Equitability. Overall, the species diversity for the 1979-80 data was higher than for the 1974-75 data (Tables 20 and 21). This is because the total number of species collected at most stations was greater in 1979-80. Equitability was also somewhat higher for the present study, although not as marked as species diversity. This indicates that although there were more species collected during the two sampling periods of the present study, the evenness of the species distributions was comparable for both studies.

(5) Faunal Similarity. Morisita's index of faunal similarity was used to compare the 1979-80 and 1974-75 data by station (Table 22). As can be seen, the level of similarity based on the number of species in common and their relative proportions is quite low for all comparisons except station 1 versus 1 for May and borrow site 1 versus 2 for May.

IV. DISCUSSION

1. Study Design Restrictions.

The accuracy of the data collected and the validity of its interpretation are dependent upon the adequacy of the study design. In order to properly assess the environmental impact of the beach nourishment program three components are necessary: (a) quantitative prenourishment base-line information; (b) immediate and short-term impact determinations; and (c) a long-term effects study. Components (a) and (b) have been addressed by other investigators (Saloman, 1976; Saloman, Naughton and Taylor, in preparation, 1982) and component (c) has been addressed by this report. The adequacy of the sampling design used for this study is discussed in Appendix D.

2. General Characterization of Abiotic Parameters.

Values for temperature, salinity, and dissolved oxygen observed in this study can be considered typical for nonestuarine northern Gulf of Mexico waters. The seasonal variations recorded for this study correspond well with those observed by Saloman (1976). Salinity and temperature were essentially uniform throughout the sampling area, and dissolved oxygen varied only slightly. Several rainstorms occurred during sampling, and small changes of salinity and water temperatures were detected at the nearshore stations and surface offshore waters. These variations were generally small and short lived due to the active mixing of waters in the surf and nearshore zones. Saloman, Naughton, and Taylor (in preparation, 1982) noted seasonal fluctuations in salinities that indicated an estuarine influence of St. Andrew Bay on some stations, possibly affecting recruitment in an unpredictable manner. Temperature extremes from winter to summer probably influence community structure by dictating reproductive seasons, but the relatively deep nearshore waters act to dampen rapid changes of water temperature. None of the physical parameters observed in this study could be considered stressful or limiting factors for faunal diversity or abundance within their observed ranges.

The sediments within the study area are very similar alongshore and at comparable distances from shore. Gorsline (1966) comments on the strikingly uniform textures of Florida's west coast, but also notes that there are specific subtle variations in specific parts of the beach. Moreover, these beach zones are periodically altered in response to surf conditions. In view of Gorsline's observations, the differences of grain-size parameters from 1974-75 to 1979-80 (Tables 9 and 10) could be attributed to small changes of exact sample location. The most notable differences in sediment composition were among the percentages of silt-clay, organic carbon, and carbonate. However, due to the extremely low levels of these three components, the differences cannot be considered biologically important and could be attributed to sampling and processing variations. The moderate wave energy of the area, together with the relatively steep-sloping nearshore zone, has resulted in a surface substrata that is almost entirely free of silt-clay sized particles and organic detritus.

3. General Faunal Characterization.

The fauna of the nearshore zone is relatively rich and diverse. The dramatic difference observed in species numbers and faunal densities between corresponding samplings of the two studies (see Figs. 9 and 10) is a function of the normal seasonal variation and not a profound alteration of community composition. The fauna of the area is well represented by the major invertebrate phyla. The following 14 species that were the dominant fauna for 1974-75 were also well represented or dominant during the present study: the polychaetes *Dispio uncinata*, *Magelona riojai*, *Paraonis fulgens*, *Sviolelepis squamata*, *Spio pettiboneae*; the bivalves *Donax texasianus*, *Ervilia concentrica*; the cumacean *Mancocuma* sp.; the amphipods *Acanthohaustorius* n. sp., *Haustorius* n. sp., *Protohaustorius* n. sp., *Pseudohaustorius* n. sp.; the anomuran *Emerita talpoida* and the cephalochordate *Branchiostoma floridae*. Many of the species collected during this and Saloman's (1976) study are new and not yet described in the literature.

Variations of species numbers and faunal densities at corresponding stations of the nine transects were observed, but there were no discernible patterns of distribution. The abundance of dominant species was nearly always the same at corresponding stations varying only in their relative proportions.

The fauna of the control stations CA and CB generally were not similar to the borrow sites B1 and B2. The borrow sites exhibited fewer species and lower faunal densities than the control site, with the exception of November-December when CA had a lower faunal density (Figs. 9 and 10). Patterns of species dominance and relative proportions of dominant species were also different (Table 14). Borrow sites seem to be most similar to transect stations 3 and 5. These differences may be attributed to the long-term effects of dredging (i.e., possible inhibition of recruitment by certain species). It should be noted that stations CA and CB are not totally acceptable controls for comparative purposes due to the large spatial separation and the deeper depths of the control sites (Fig. 1). Also, data from the transect stations have shown that species composition and faunal densities vary with distance from shore. Therefore, dredging effects at the borrow sites are unclear.

4. Sediment-Fauna Relationships.

Substratum type is generally considered the most important factor influencing the distribution of benthic organisms (Peterson, 1913, 1915, 1918; Jones, 1956; Thorson, 1957; Sanders, 1958; McNulty, Work, and Moore, 1962; Buchanan, 1963; Nichols, 1970; Young and Rhoads, 1971; Johnson, 1971; Bloom, Simon, and Hunter, 1972; Collard and D'Asaro, 1973; Pearson, 1975; Probert, 1975; Conner and Simon, 1979).

As a result of the moderate wave energy in the study area, the nearshore sediments experience an almost constant agitation. This agitation is reflected in the type of fauna inhabiting the substratum, most being active burrowers or crawlers capable of reentering the sediments quickly if displaced. There were no species present which require a permanent attachment site and there were few permanent tube dwellers. There were no strong statistical corrrelations between the various sediment parameters (mean grain size, percent silt-clay, organic carbon) and faunal parameters (number of species, faunal density). Physical processes such as wave

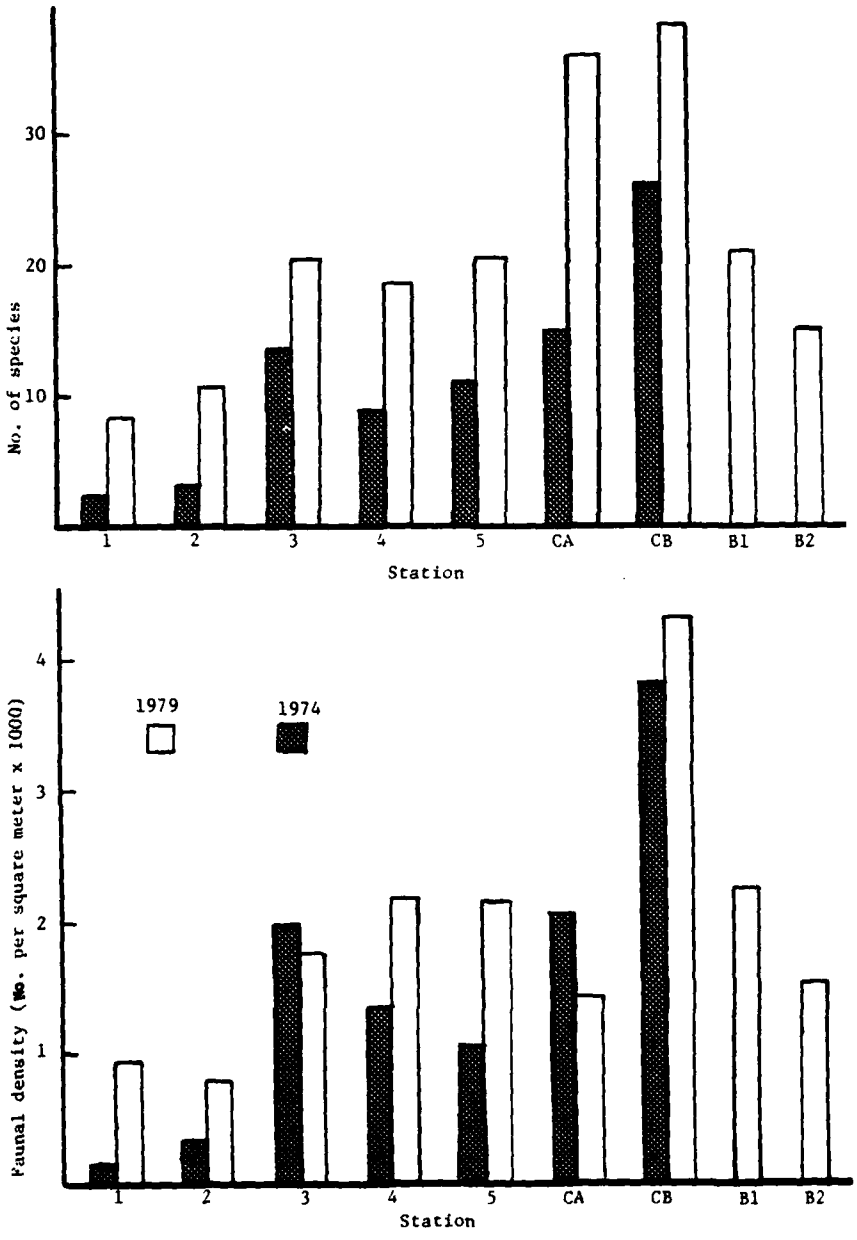

Figure 9. Graphic comparisons of numbers of species and faunal densities between November 1974 and November-December 1979.

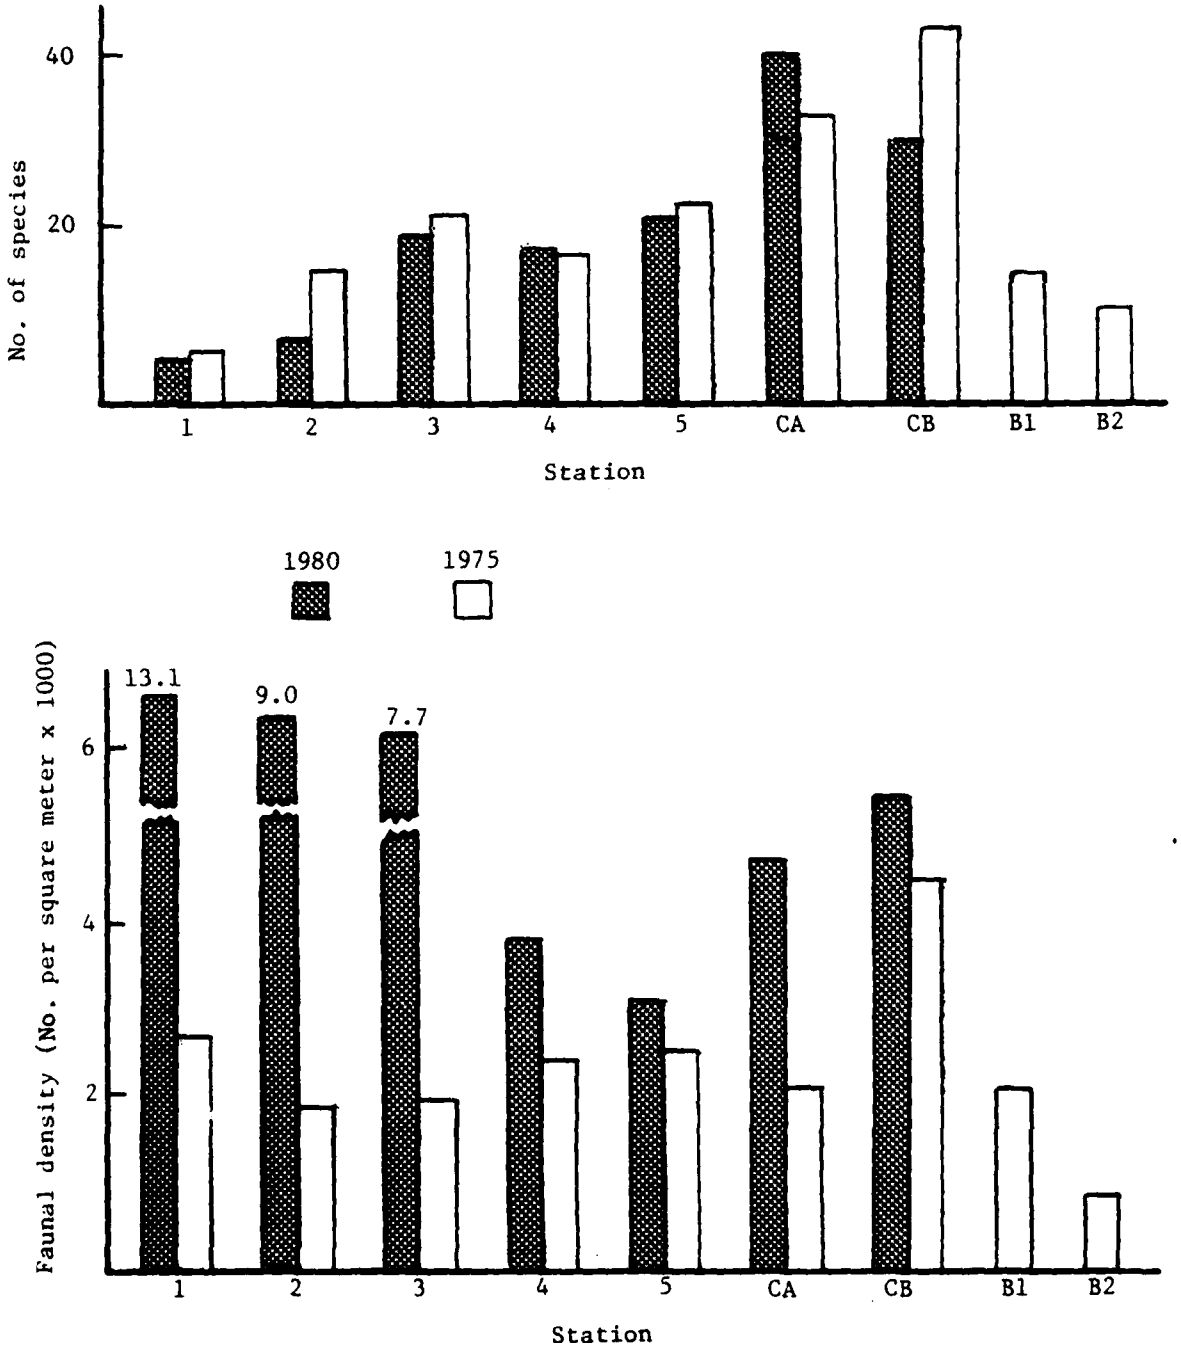

Figure 10. Graphic comparison of numbers of species and faunal densities between May 1975 and May 1980.

energy and longshore currents are probably responsible for the distributional patterns of the nearshore fauna.

5. Comparison of Abiotic and Biotic Parameters Between 1979-80 and 1974-75.

Temperature, salinity, sediment grain-size distribution, organic carbon, and carbonate content showed little variation between 1979-80 and 1974-75. The borrow sites which were not sampled in 1974-75 showed similarities to the control stations for these abiotic parameters. Apparently, the borrow pits initially filled with fine sandy sediments including elevated levels of silt-clay (Saloman, Naughton, and Taylor, in preparation, 1982). However, based on current data the borrow pits have returned to a texture comparable to surrounding areas. Moderate wave action and high longshore transport rates (Balsillie, 1975) probably account for the rapid filling of the borrow pits.

Although community parameters (namely, species richness, faunal density, diversity, and equitability) indicate that most of the stations had a different community composition in 1979-80 than in 1974-75, interpretation of the data considering seasonal and spatial variations indicates that the fauna of the area is drawn from a common pool of "available" species. Therefore, the changes in community composition encountered in this study cannot be attributed to beach nourishment activities. Seasonal variations are known to be significant in most parts of the Gulf of Mexico and adjacent estuarine waters (Livingston, 1976; Livingston, et al., 1976; Simon, 1977; Mahadevan, et al., 1977; Culter, et al., 1981).

6. Long-Term Effects of Beach Nourishment.

Based on the data and findings of this study, it is concluded that the beach nourishment program conducted during 1976 on the Panama City and adjacent beaches has not manifested any long-term discernible effects on the benthic infauna or the surface nearshore sediments.

V. SUMMARY AND CONCLUSIONS

A study of benthic macrofauna and sediments was conducted in the nearshore zone of the area between West Pass and Philips Inlet at Panama City Beach, Florida, in the northeastern Gulf of Mexico. Samples of surface sediments and fauna were collected from 28 November to 1 December 1979 and from 19 to 23 May 1980. Forty-seven stations, located on nine east-west transects, and two dredged borrow sites were sampled.

Temperature, salinity, and dissolved oxygen were measured at each station and found to vary seasonally. There was very little spatial variation of these parameters. Temperature ranged from 16.5° to 26.0° Celsius; salinity ranged from 29.0 to 35.5 parts per thousand; and dissolved oxygen ranged from 4.8 to 8.6 parts per million. Substrata within the study area consisted of fine to medium, coarse quartz sands, with very low levels of silt-clay, percent organic carbon, and percent carbonate. The abiotic parameters collected during this study were similar to Saloman's (1976) measurements. Sediment grain-size parameters were also generally comparable, with the major differences occurring in percentages of silt-clay, organic

carbon and carbonate. These differences are attributable to natural variations as well as sampling and processing variability.

The greatest numbers of species were found in May at the stations seaward of the second sandbar. Faunal density was, on the average, greatest during November-December at stations 4 and 5, with all other stations exhibiting greatest densities during May. The benthic fauna was well represented by the major invertebrate types with polychaetes, crustaceans and bivalves being dominant. The most abundant organisms were generally active burrowing and crawling types. Diversity and equitability values were lowest at stations influenced by wave action (stations 1, surf zone; 2, first sandbar; 4, second sandbar) and highest at stations 3, 5, CA and CB (3, between first and second sandbar; 5, CA and CB beyond second sandbar). Diversity values ranged from 0.15 to 3.22 with the highest values generally occurring in November-December.

The fauna and community parameters of the present study were compared to Saloman's (1976) study. It was determined that the communities of 1979-80 were different from the communities of 1974-75, but that this variation could be attributed to temporal fluctuations.

Borrow sites B1 and B2 were found to have lower species richness and faunal densities than stations CA and CB for both sampling periods, with the exception of station CA, which had a lower faunal density in November-December. The borrow sites also exhibited lower diversity and equitability than stations CA and CB for both sampling periods. Overall, the borrow sites seemed to be most similar to transect stations 3 and 5.

The Morisita's index of faunal similarity was used to compare the station data for the 1979-80 and 1974-75 studies. Only two highly similar comparisons were found: station 1 for the May 1980 collections and borrow sites B1 versus B2 for May 1980.

No long-term adverse environmental effects as a result of beach nourishment could be detected within the nearshore zone of the Panama City beaches. There were also no adverse or stressful conditions present at the borrow sites. These conclusions are based on the analysis of benthic macroinfauna and surface sediment analyses for November-December 1979 and May 1980 and the comparison of these data to Saloman's (1976) study.

APPENDIX D

STUDY DESIGN RESTRICTIONS

APPENDIX D

STUDY DESIGN RESTRICTIONS

The primary purpose of this study was to collect data on the benthic macroinfauna and the surface sediments to evaluate the long-term effects of beach nourishment and associated dredging activities. Inherent in any environmental study are limitations on the quantity and types of data that can be collected. A good study plan requires that the data collected enable the investigators to differentiate between manmade and natural perturbations. If no effects can be detected, then by definition there has been no environmental harm. This emphasizes the need to conduct scientifically valid studies utilizing best applicable methodologies. Potential limiting factors encountered in this study are discussed below.

Sampling Design Adequacy.

The accuracy of the data collected for the present study and the validity of the interpretations and comparisons made to the base-line study (Saloman, 1976) are dependent on the adequacy of the sampling design. Some of the key factors in establishing sampling and analysis adequacy are:

(a) Reliability and accuracy of sampling device (consistent substrate penetration, no loss of sample during retrieval, etc.). Characteristics for a good sampling device are described by Menzies and Rowe (1968) and Holme and McIntyre (1971).

(b) Adequate sieve size to retain a majority of the macrofauna (Reish, 1959).

(c) Good and consistent procedures to ensure proper preservation of fauna.

(d) Adequate number of stations to determine spatial varability of fauna.

(e) Sufficient replication to adequately describe both the within-station faunal variation, and the majority of the species inhabiting the site.

(f) Sufficient temporal frequency of sampling to address seasonal variations in fauna.

(g) The use of identical or comparable methodologies for both prenourishment and postnourishment studies.

(h) Sound taxonomic procedures and use of expert confirmations to ensure accurate identification of organisms.

(i) Consistent data analysis procedures.

The present study addressed the above criteria as follows to ensure the collection of an adequate, quantitative data base:

(a) A diver-operated core was utilized to ensure consistent penetration and the collection of samples satisfying the criteria defined by Menzies and Rowe (1968). The core is generally considered a better device than conventional grabs (Word, Kauwling, and Mearns, 1976; Swartz, 1978).

(b) A 0.701-millimeter mesh sieve was utilized to wash the samples. This sieve size was considered by Saloman (personal communication, 1979) to be adequate for collecting a majority of the macrofauna within the study area. Other studies have shown that a 0.5-millimeter mesh sieve is often necessary for quantitative benthic collections (Reish, 1959; Mahadevan and Patton, 1979). A quantitative comparison of the two sieve sizes for the study area would be necessary to compare the results with other studies that used the smaller mesh size.

(c) Fixing and preserving methods were consistent and followed acceptable procedures in the literature.

(d) A total of 49 stations were sampled during the present study, 47 of which were sampled for the 1974-75 prenourishment study. These stations encompass the nearshore zone, from the swash area to just beyond the second sandbar. In view of the low variability in numbers and species of animals at corresponding stations for the 9 transects, the 47 stations are believed to adequately sample the nearshore zone. However, the study did not totally address the area most likely to receive fine sediments resuspended by dredging activities, i.e., the area beyond the second sandbar at depths of 9 to 10 meters. Stations CA and CB were the only control areas at these depths. Optimal sampling strategy would have required control stations placed in close proximity to the borrow sites. Unfortunately, the borrow sites were not selected prior to Saloman's (1976) study.

(e) Four replicates were analyzed from each station. Species saturation curves (Gleason, 1922; Holme, 1953) were constructed for 5 stations for 12 replicates by Saloman (1976). Based on those curves it was determined that four cores adquately sampled the fauna of the study area. Species area curves were constructed for the present study for transect 5, stations 1-5, stations CA and CB, and borrow sites B1 and B2. These curves are presented in Figures D1 to D5. Each curve is the average of two randomly chosen combinations of replicate order. Only one-third (6) of the plots indicate adequate replication (criterion: increase between replicates 3 and 4 less than or equal to 10 percent). An additional replicate sample at each station would probably have resolved this problem. The four replicates analyzed give a total surface sampling area of 0.064 square meters. For most benthic studies, 0.1 square meter is considered a sufficient sample size (Holme and McIntyre, 1971). However, based on Saloman's (1976) species saturation curves and those generated for this study, these data have been determined to be adequate for comparative purposes.

(f) To determine variations due to seasonal influences, samples were collected for two seasons, November-December 1979 and May 1980. Significant differences were found in all of the faunal parameters as well as species composition between sampling periods. Saloman (1976) also revealed pronounced seasonal fluctuations. Physical parameters such as temperature and wave intensity show pronounced seasonal variation within the study area and undoubtedly influence infaunal community characteristics within the nearshore zone. The two sampling periods of this study do not adequately address temporal variations. However, in conjunction with Saloman's (1976) data (four seasonal samplings) the importance of seasonal variation was assessed.

(g) To make valid comparisons of studies conducted at different times or places, the methods used should be identical, where practical, or yield analogous results. All the sampling and processing methods used for this study were identical to those used by Saloman with the following exceptions:

(1) A 5.08-centimeter PVC core was used to obtain sediment samples instead of 8-ounce (227 grams) jars.

(2) Percent organic carbon and percent carbonate present in the sediment samples were determined by combustion (500° Celsius for organic carbon and 1,000° Celsius for carbonate). Saloman (1976) used a Leco 750-100 90-second carbon analyzer. These methods have been shown to yield comparable results (Carver, 1971).

(h) Taxonomic procedures followed standard literature keys and expert confirmations. Additionally, a reference collection of species collected during the 1974-75 study was provided for comparative purposes.

(i) Sediment samples have been analyzed by standard geological methods, tabulated and summarized for each station. Analytical methods and numerical indices were chosen on the basis of their widespread use in scientific literature and their ability to provide data summaries.

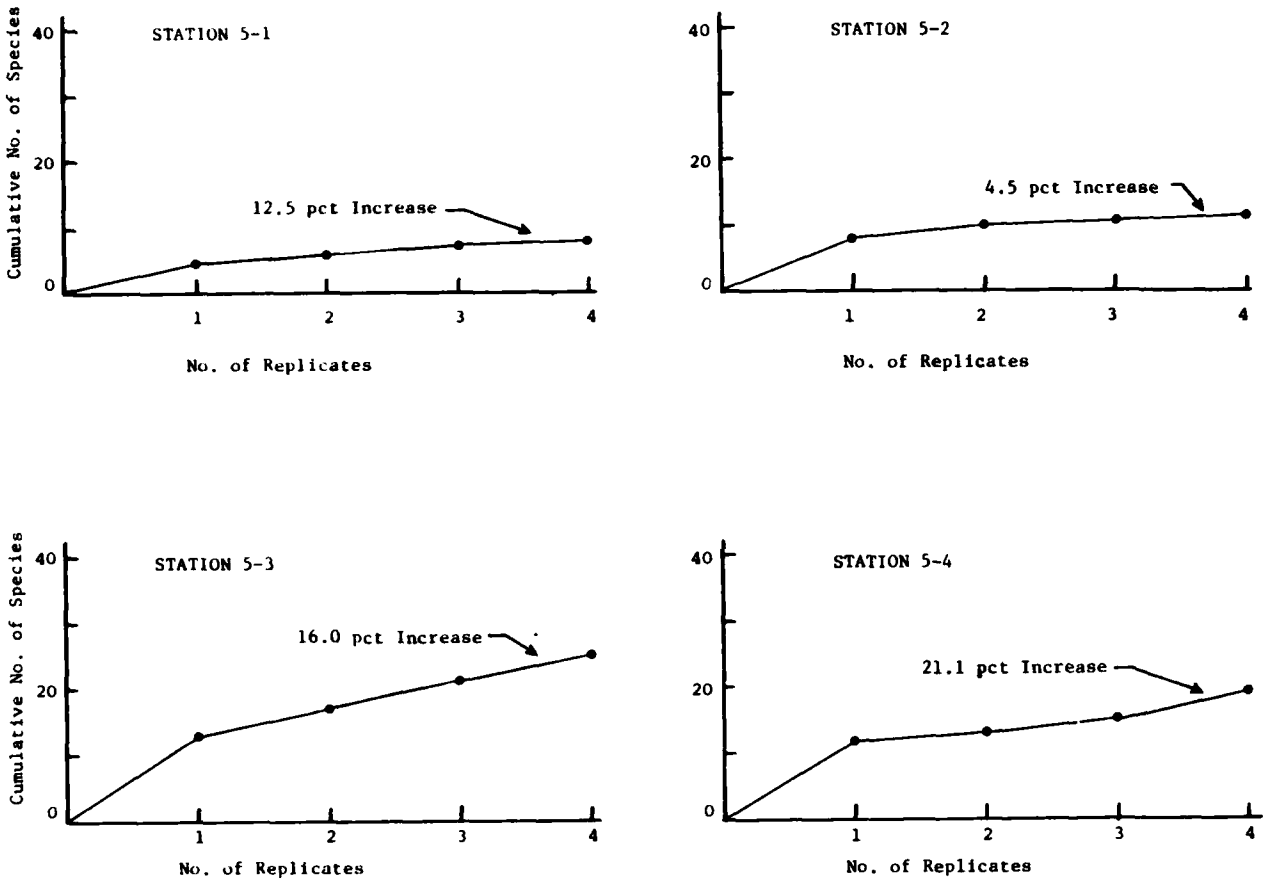

Figure D-1. Species area curves for stations 1 to 4 of transect 5 for the November-December 1979 sampling.

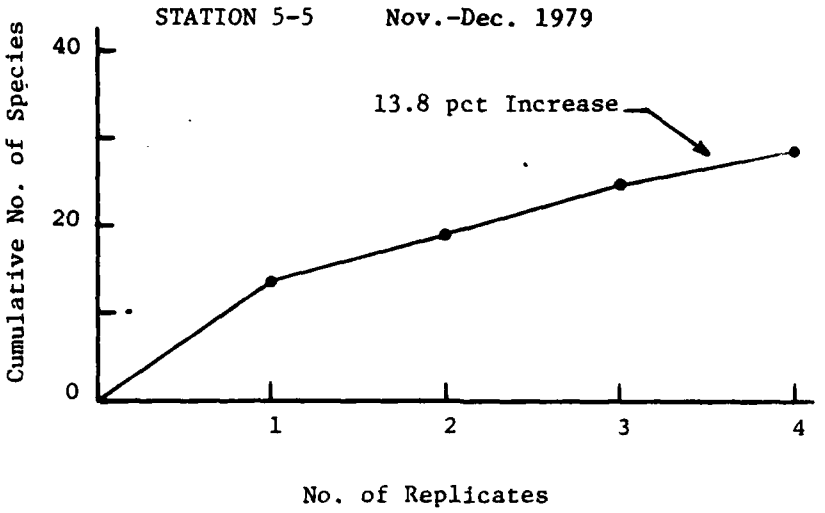

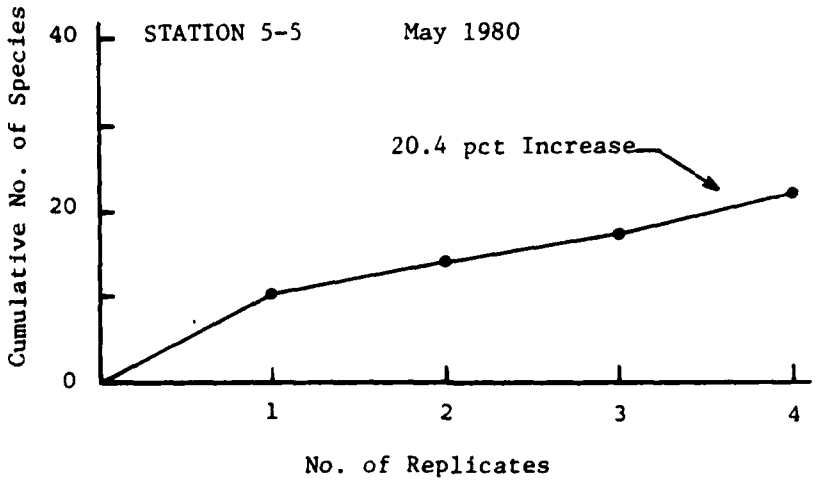

Figure D-2. Species area curves for station 5 of transect 5 for the November-December 1979 and May 1980 samplings.

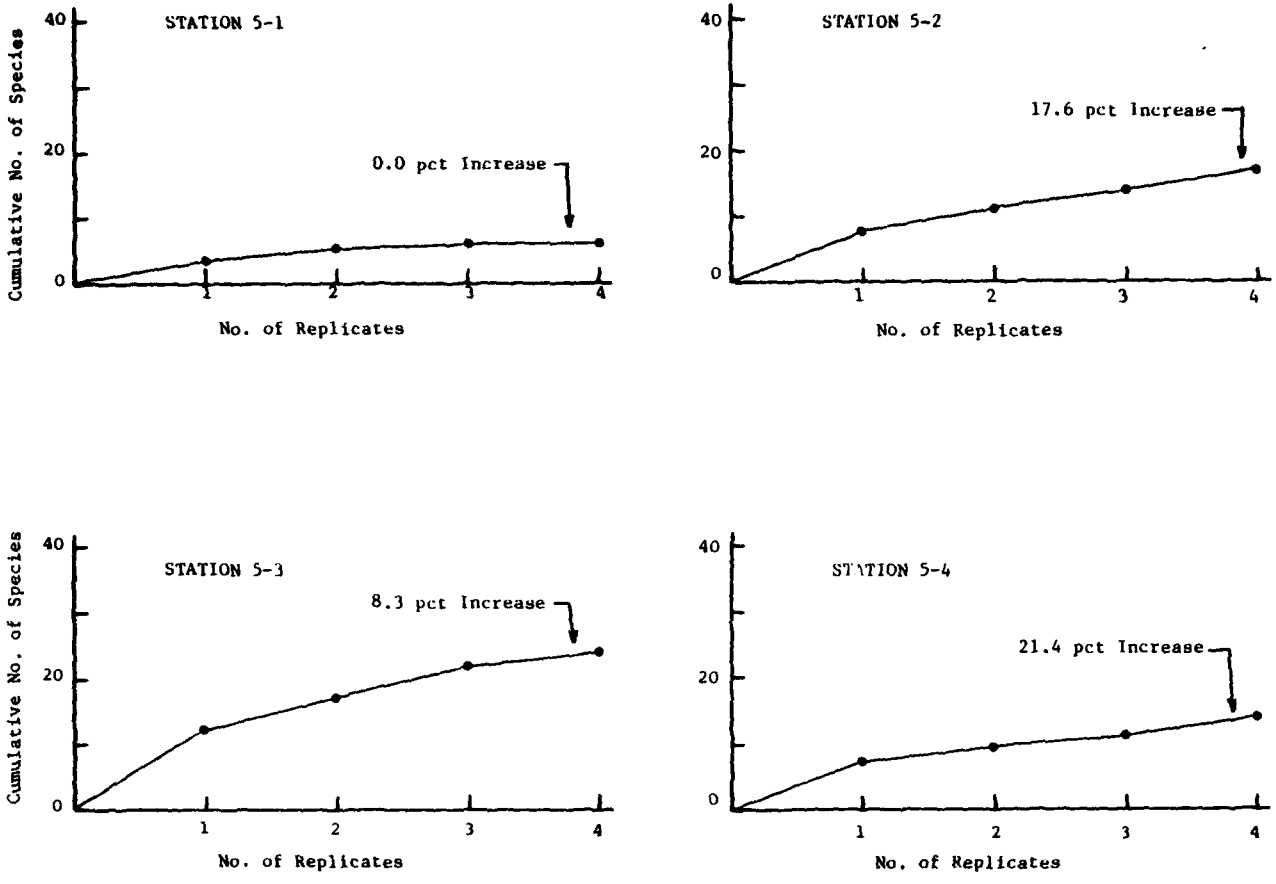

Figure D-3. Species area curves for stations 1 to 4 of transect 5 for May 1980.

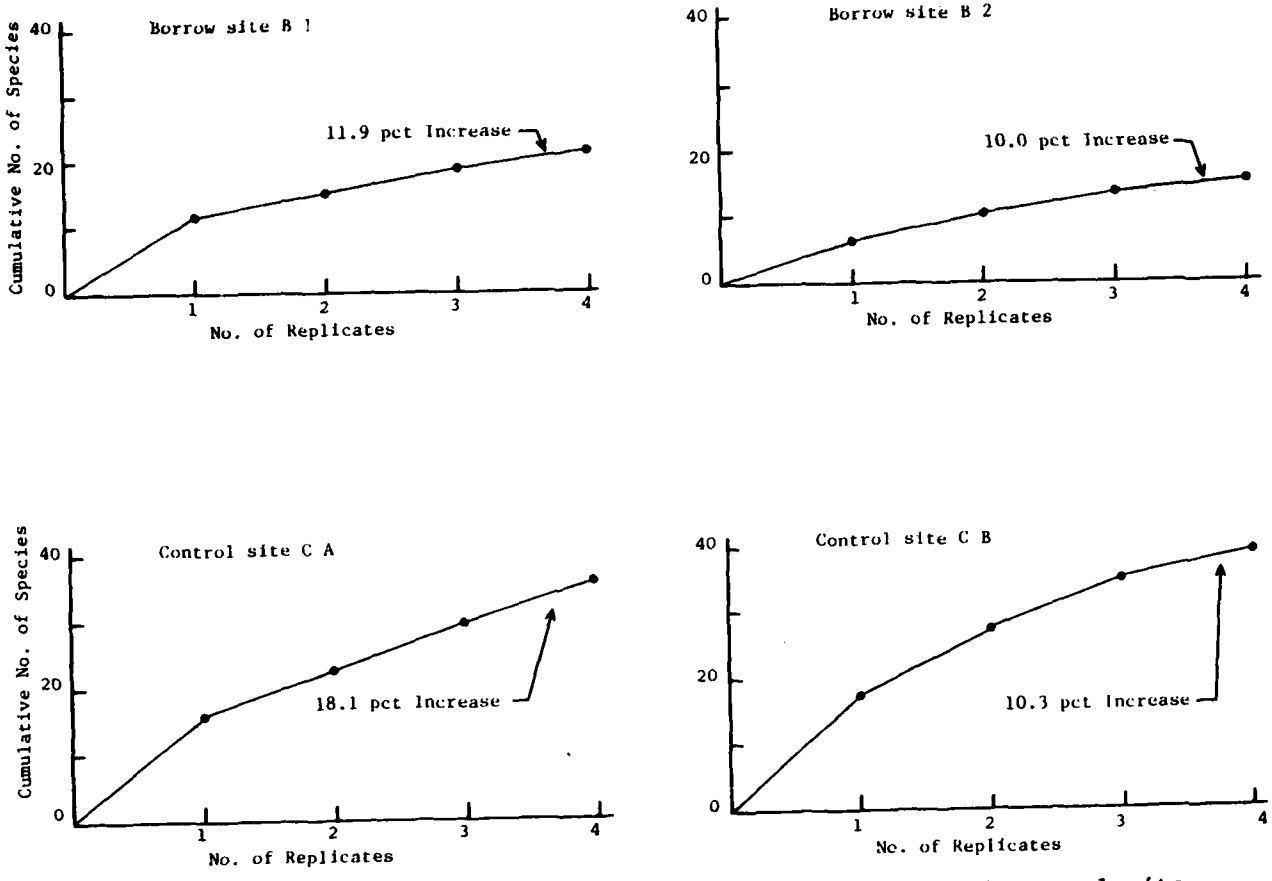

Figure D-4. Species area curves for bottom sites B1 and B2 and control sites CA and CB for the November-December 1979 sampling.

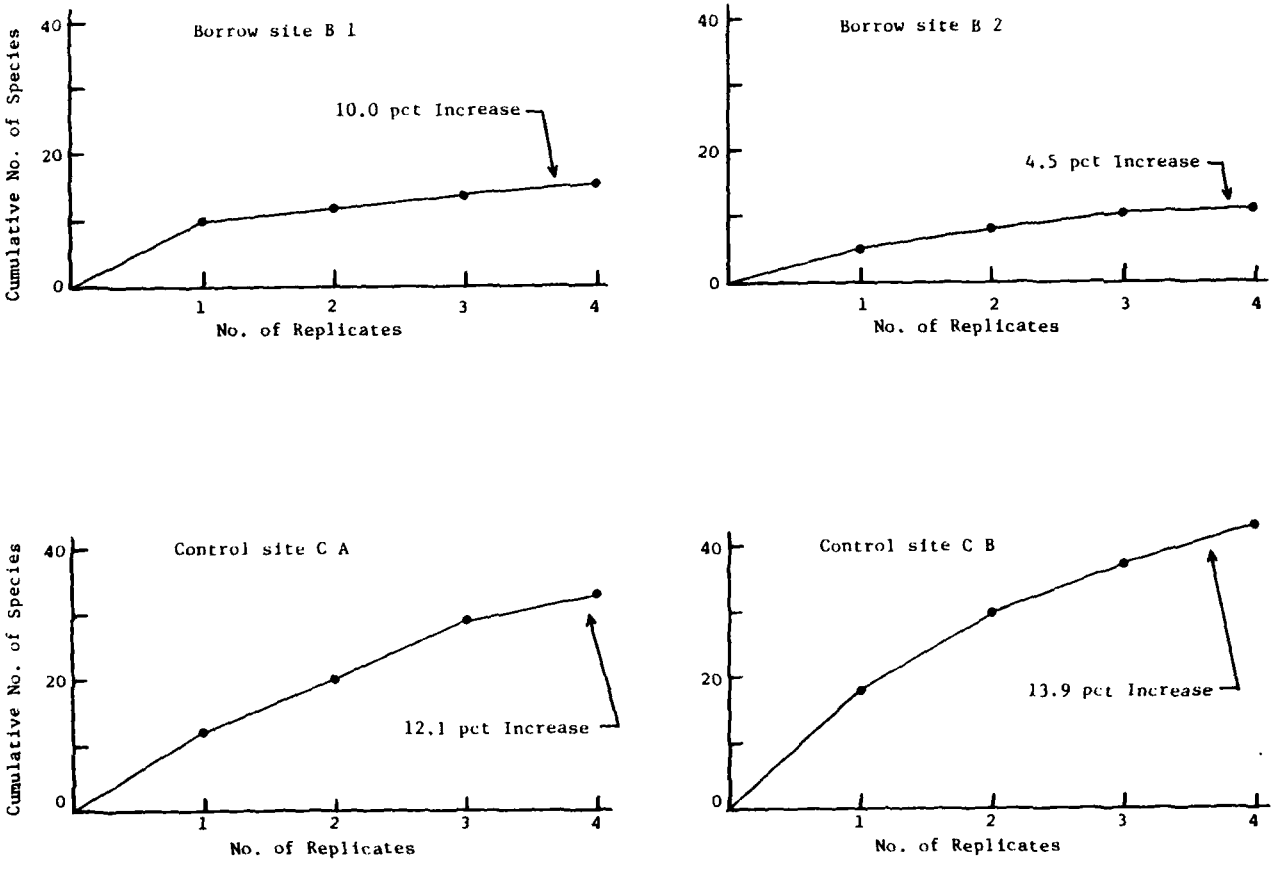

Figure D-5. Species area curves for borrow sites B1 and B2 and control sites CA and CB for May 1980.
